**ABSTRACT:** Bacteriorhodopsin (BR) and halorhodopsin (HR) are light-driven proton and chloride ion pumps, respectively, in *Halobacterium salinarum*. The amino acid identity of these proteins is about 25%, suggesting that each has been optimized for their own functions during evolution. However, it is known that the BR mutants, D85T and D85S, can pump chloride ions. This fact implies that the Schiff base region is important in determining ionic selectivity. The X-ray crystallographic structure of D85S(Br<sup>−</sup>) showed the presence of a bromide ion in the Schiff base region (Facciotti, M. T., Cheung, V. S., Nguyen, D., Rouhani, S., and Glaeser, R. M. (2003) *Biophys. J.* 85, 451–458). In this article, we report on the study of hydrogen bonds of the Schiff base and water molecules in D85S in the absence and presence of various halides, assigning their N–D and O–D stretching vibrations in D<sub>2</sub>O, respectively, in low-temperature Fourier-transform infrared (FTIR) spectroscopy. We found that the hydrogen bond of the Schiff base in D85S(Cl<sup>−</sup>) is much stronger than that in HR, being as strong as that in wild-type BR. Similar halide dependence in D85S and in solution implies that the Schiff base forms a direct hydrogen bond with a halide, consistent with the X-ray structure. Photoisomerization causes a weakened hydrogen bond of the Schiff base, and halide dependence on the stretching frequency is lost. These spectral features are similar to those in the photocycle of proton-pumping BR, though the weakened hydrogen bond is more significant for BR. However, the spectral features of water bands in D85S are closer to chloride-pumping HR because O–D stretching vibrations of water are observed only at >2500 cm<sup>−1</sup>. Unlike in BR, we did not observe strongly hydrogen-bonded water molecules for halide-pumping D85S mutants. This observation agrees with our recent hypothesis that strongly hydrogen-bonded water molecules are required for the proton-pumping activity of archaeal rhodopsins. Hydrogen-bonding conditions in the Schiff base region of D85S are discussed on the basis of the spectral comparison with those of wild-type BR and HR.

Photosynthesis in some archaea involves two rhodopsins that do not utilize electron-transfer reactions. Bacteriorhodopsin (BR)<sup>1</sup> and halorhodopsin (HR) in *Halobacterium salinarum* function as light-driven proton and chloride pumps, respectively (1–4). The chromophore of these proteins is all-trans retinal that binds to a lysine residue through a Schiff base linkage, and the all-trans to 13-cis photoisomerization triggers the pumping process. Extensive studies on BR have suggested the mechanism for unidirectional translocation of protons (1, 2). In contrast, the molecular mechanism of chloride transport in *Halobacterium salinarum* HR (sHR) and a homologous HR from *Natronomonas pharaonis* (pHR) is still poorly understood.

In 1995, Sasaki et al. reported that the replacement of the amino acid at position 85 from Asp to Thr converts BR from a proton to chloride pump (5). Later, it was found that the D85S mutant more strongly binds chloride and also pumps chloride ions (6). D85T and D85S also pump other halide ions as well as HR. In the absence of halide, the absorption maximum of D85S is located at about 600 nm (7). Halide binding to D85S shifts the absorption maximum at about 570 nm, apparently because the halide becomes the counterion of the protonated Schiff base.

Figure 1 shows the Schiff base region of BR (8), D85S mutant in the absence (9, 10) and presence of Br<sup>−</sup> (11), and sHR (12). The structure of the Schiff base region is similar in BR and sHR. It contains a quadrupole with positive charges located at the protonated Schiff base and Arg82 (Arg108 in sHR) and counterbalancing negative charges located at Asp85 (chloride ion in sHR) and Asp212 (Asp238 in sHR). Such structural similarity could lead to the functional interconversion from a proton to chloride ion pump in BR. However, the Schiff base region of D85S is considerably different from that of BR and sHR (Figure 1). The hydrogen-bonding acceptor of the Schiff base is a water molecule in BR and sHR, whereas the N–H group of the

<sup>1</sup> Abbreviations: BR, bacteriorhodopsin; sHR, *salinarum* halorhodopsin; pHR, *pharaonis* halorhodopsin; FTIR, Fourier-transform infrared; 5-FOA, 5-fluoroorotate.

stretches of water were assigned by comparing spectra in D<sub>2</sub>O and D<sub>2</sub><sup>18</sup>O. Although the difference in the frequency between C=NH and C=ND stretching vibrations did not show halide dependence, clear halide dependence was observed for the N–D stretching vibration of the Schiff base in D85S as well as in solution. We conclude that the Schiff base forms a direct hydrogen bond with halide in the unphotolyzed state of D85S, as in the X-ray crystal structure (11). Strongly hydrogen-bonded water molecules are not present in D85S regardless of the absence or presence of halides. Hydrogen-bonding conditions in the Schiff base region of D85S are discussed on the basis of the present FTIR spectral analysis.

## MATERIALS AND METHODS

**Plasmid Constructs and Site-Directed Mutagenesis.** A fragment containing the *bop* gene (1.6 kbp) was amplified by PCR and cloned into the vector pGEM-T easy (Promega) using the primer set (5'-ggatccGACGTGAAGATGGGGC-3', 5'-ggatccGTGACCGTTCGATGC-3'). A cloned fragment was confirmed for its sequence and then transferred to the vector pUC18 for mutagenesis or the vector pMPK54 for transformation (29), which contains a gene conferring resistance to the 3-hydroxy-3-methylglutaryl CoA reductase inhibitor simvastatin in *H. salinarum*. A point mutation (Asp85 → Ser) was introduced into the *bop* gene by PCR mutagenesis (Stratagene), and resultant mutation was confirmed by sequencing the plasmids prior to the transformation of *H. salinarum*.

**Transformation for *H. salinarum* and Cultivation for Isotope Labeling.** *H. salinarum* strains MPK409 (29) were transformed using the plasmid described above. The transformation procedure was essentially the same as that described in a previous article (30). Briefly, 10 mL of early log phase cells were collected by centrifugation (6000 g, 10 min) and resuspended in 2 mL of spheroplasting solution. Then, 100 mL aliquots were added to 10 mL of 0.5 M EDTA in spheroplasting solution and gently mixed. After 20 min, 3–5 mg of plasmid DNA in 10 mL was added and incubated for a further 10 min. Equal volumes (140 mL in this case) of 60% poly(ethylene glycol) 600 in spheroplasting solution was added and mixed by gently tilting the tube back and forth. After 20 min of additional incubation, 1 mL of regeneration salt solution was added. The cells were pelleted in a microcentrifuge at 5000 rpm for 5 min, and to the resultant pellet, 1 mL of complex culture medium containing 15% sucrose was added. After incubation for 48 h at 37 °C, 100  $\mu$ L samples were spread on plates containing 15% sucrose and 10  $\mu$ g/mL simvastatin. After 10 days of incubation at 40 °C, purple colored colonies were picked and grown in complex culture medium with 10 mg/mL of simvastatin, and after incubation for 24 h at 37 °C, 100 mL samples were spread on plates containing 250  $\mu$ g/mL of 5-FOA. After a week of incubation, purple colonies were picked and grown again in complex culture medium containing 50  $\mu$ g/mL of uracil. For preparing [ $\zeta$ -<sup>15</sup>N]L-Lys-labeled sample, [ $\zeta$ -<sup>15</sup>N]L-Lys (0.1 g/L) was replaced by unlabeled L-Lys in the amino acid synthetic growth medium (31) containing 50  $\mu$ g/mL of uracil. The purple membranes were isolated and purified in the usual manner (32).

**Sample Preparation for FTIR Measurements.** Samples were prepared in 2 mM citrate buffer (pH 5.0) in the presence

of 1.6 mM Na<sub>2</sub>SO<sub>4</sub>, 5 mM NaCl, NaBr, and NaI and centrifuged three times to replace each halide (22). A 120  $\mu$ L aliquot of the sample was dried on a BaF<sub>2</sub> window with a diameter of 18 mm. After hydration by 1  $\mu$ L of H<sub>2</sub>O, D<sub>2</sub>O, or D<sub>2</sub><sup>18</sup>O, the sample was placed in a cell and then mounted on an Oxford DN-1704 cryostat. Absorption maxima of the hydrated films were at 596 nm in the absence of halide and at 565, 566, and 561 nm in the presence of Cl<sup>−</sup>, Br<sup>−</sup>, and I<sup>−</sup>, respectively. The hydrated film was illuminated with >500 nm light for 2 min at 230 K to obtain the light-adapted state of D85S.

Low-temperature FTIR spectroscopy was applied as described previously by using a Bio-Rad FTS-40 FTIR spectrometer (20–26). Because the orientation of molecules in hydrated films was not good, we did not use an IR polarizer in the FTIR measurements, and the sample films were not tilted in the cryostat. The K minus D85S spectra were measured by photoconversion between the K and unphotolyzed states at 130 K (20, 21, 23–25). Spectral resolution was 2 cm<sup>−1</sup>, and 40 spectra of 128 interferograms were averaged. The spectral features were similar to those of the wild type in the 1800–800 cm<sup>−1</sup> region, indicating the formation of the K intermediate. Each spectrum was normalized at the 1202 cm<sup>−1</sup> (−) band because of the C–C stretch of the retinal chromophore. The spectra of D85S-(free) are shown without changing the amplitude, whereas those for D85S(Cl<sup>−</sup>) and D85S(Br<sup>−</sup>) were multiplied by a factor of 0.7, and those for D85S(I<sup>−</sup>) were multiplied by a factor of 1.2.

## RESULTS

**Assignment of the C=N Stretching Vibration of the Protonated Schiff Base in D85S and Its K Intermediate.** In this study, we prepared the [ $\zeta$ -<sup>15</sup>N]Lys-labeled D85S samples to assign vibrational modes of the protonated Schiff base. It is noted that <sup>15</sup>N-labeling did not cause any substantial changes in other bands. Figure 2 shows the spectral changes in the frequency region of the C=N stretching mode of the retinal Schiff base in H<sub>2</sub>O, where the isotope-sensitive bands can be assigned as C=NH stretching vibrations of the Schiff base. In the wild type of BR, the C=N stretching vibrations were reported to be 1641 and 1608 cm<sup>−1</sup> for the unphotolyzed and K states, respectively, by means of FTIR spectroscopy (33). In D85S, the intensities of the broad negative bands at 1632 (free), 1632 (Cl<sup>−</sup>), 1631 (Br<sup>−</sup>), and 1629 (I<sup>−</sup>) cm<sup>−1</sup> are significantly reduced in the [ $\zeta$ -<sup>15</sup>N]Lys-labeled D85S sample (Figure 2A). From the double difference spectra, which subtracts the labeled spectra from unlabeled ones (Figure 2B), we assigned the C=NH stretch in the unphotolyzed state of D85S as shown in Table 1. Earlier FTIR spectroscopy of sHR also reported that the C=NH stretching vibrations of the Schiff base differ among halides (18).

Upon formation of the K intermediate, positive peaks appear in the 1620–1600 cm<sup>−1</sup> region (Figure 2A). The two peaks that exhibit isotope shift from the [ $\zeta$ -<sup>15</sup>N]Lys-label, the bands at 1622 and 1612 cm<sup>−1</sup>, are candidates for the C=NH stretch of the K intermediate of D85S(Cl<sup>−</sup>). It should be noted that the C=O stretch of the peptide carbonyl (amide I vibration) of Val49 appears at 1623 (+)/1617 (−) cm<sup>−1</sup> for wild-type BR (34). Spectral shapes of D85S at around

<sup>a</sup> From ref 32. <sup>b</sup> From ref 21.

1620 cm<sup>-1</sup> (Figure 2A) are similar to that of the wild type, suggesting that the same amide-I bands of Val49 are involved in the spectra of D85S. Therefore, we examined the double difference spectrum, where the contribution of amide-I bands is canceled. Figure 2B shows two positive peaks, between which a higher frequency band (1621 cm<sup>-1</sup>) originates from the C=<sup>15</sup>NH stretch of the unphotolyzed state as judged from the original spectra (dotted lines in Figure 2A). Thus, we assigned the C=NH stretches of the K intermediate in D85S at 1614 (free), 1612 (Cl<sup>-</sup>), 1611 (Br<sup>-</sup>), and 1611 (I<sup>-</sup>) cm<sup>-1</sup> (Table 1).

Figure 3 shows the spectral changes in the frequency region of the C=ND stretching mode of the retinal Schiff base in D<sub>2</sub>O, where the isotope-sensitive bands can be assigned as C=ND stretching vibrations of the Schiff base. In wild type BR, the C=ND stretching vibrations were reported to be 1628 and 1606 cm<sup>-1</sup> for the unphotolyzed

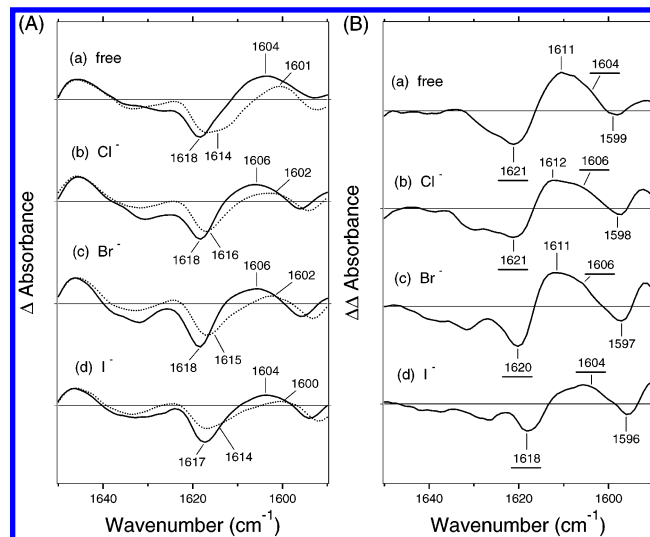

FIGURE 3: (A) K minus D85S difference infrared spectra of halide-free (a), Cl<sup>-</sup>-bound (b), Br<sup>-</sup>-bound (c), and I<sup>-</sup>-bound (d) D85S in the 1770–1560 cm<sup>-1</sup> region. Unlabeled (—) and [ζ-<sup>15</sup>N]Lys-labeled (....) D85S samples were hydrated with D<sub>2</sub>O, and spectra were measured at 130 K. One division of the y axis corresponds to 0.002 absorbance units. (B) Double difference spectra of [ζ-<sup>15</sup>N]Lys-labeled and unlabeled samples, where the spectra of the labeled D85S are subtracted from those of the unlabeled D85S in panel A. Underlined frequencies of the negative and positive bands correspond to the C=ND stretching vibrations in the unphotolyzed and K states, respectively.

and K states, respectively, by means of FTIR spectroscopy (33). As described above, the amide-I bands of Val49 appear at 1623 (+)/1617 (–) cm<sup>-1</sup>, which do not shift in D<sub>2</sub>O. For this reason, the negative peaks at 1617 to 1618 cm<sup>-1</sup> may not represent the C=ND stretch of the Schiff base accurately. Figure 3B shows double difference spectra between unlabeled and [ζ-<sup>15</sup>N]Lys-labeled D85S. From the negative peak at around 1620 cm<sup>-1</sup>, we assigned the C=ND stretch in the unphotolyzed state of D85S at 1621 (free), 1621 (Cl<sup>-</sup>), 1620 (Br<sup>-</sup>), and 1618 (I<sup>-</sup>) cm<sup>-1</sup> (Table 1).

Upon the formation of the K intermediate, positive peaks appear in the 1610–1590 cm<sup>-1</sup> region, which exhibit spectral downshift by [ζ-<sup>15</sup>N]Lys-labeling (Figure 3A). Therefore, we assigned the C=ND stretch in the K intermediate of D85S at 1604 (free), 1606 (Cl<sup>-</sup>), 1606 (Br<sup>-</sup>), and 1604 (I<sup>-</sup>) cm<sup>-1</sup> (Table 1). The double difference spectra in Figure 3B also support the assignment.

From <sup>15</sup>N-isotope labeling of the side chain of lysine, we assigned the C=NH and C=ND stretches of the Schiff base in the unphotolyzed and K states of D85S. Figure 4 shows infrared difference spectra of D85S hydrated with H<sub>2</sub>O (solid lines) and D<sub>2</sub>O (dotted lines), where the tagged frequencies in the 1650–1600 cm<sup>-1</sup> region originate from C=NH and C=ND stretches of the Schiff base, respectively. Interestingly, the frequency difference between C=NH and C=ND stretching vibrations in the unphotolyzed state (11 cm<sup>-1</sup>) is not halide dependent, which has been regarded as the marker of the hydrogen-bonding strength of the Schiff base (Table 1). According to the X-ray crystal structure (Figure 1), the N–H group of the Schiff base forms a direct hydrogen bond with Br<sup>-</sup>. This suggests that other halides such as Cl<sup>-</sup> and I<sup>-</sup> occupy the same position as that of Br<sup>-</sup>. If this is the case, could the hydrogen-bonding strength of the Schiff base be identical among different halides? In addition, the value

FIGURE 4: K minus D85S difference infrared spectra of halide-free (a),  $\text{Cl}^-$ -bound (b),  $\text{Br}^-$ -bound (c), and  $\text{I}^-$ -bound (d) D85S in the 1770–1560  $\text{cm}^{-1}$  region. The samples were hydrated with  $\text{H}_2\text{O}$  (—) or  $\text{D}_2\text{O}$  (····), and spectra were measured at 130 K. One division of the y axis corresponds to 0.002 absorbance units.

(11  $\text{cm}^{-1}$ ) is also identical to that measured in halide-free D85S. According to the X-ray crystal structure of the free form (Figure 1), a water molecule is a hydrogen-bonding acceptor of the Schiff base. Although D85S(free) lacks a negative charge in the Schiff base region, is the hydrogen-bonding strength of the Schiff base with water identical to that with halides? As we showed previously (21), the N–D stretching vibration in  $\text{D}_2\text{O}$  is a more direct probe of hydrogen-bonding strength, and more detailed information will be gained. We analyze the N–D stretches in the following section.

Figure 4 provides different information about D85S. The 1750–1700  $\text{cm}^{-1}$  region is characteristic of frequencies of the C=O stretch of protonated carboxylic acids. Figure 4 shows the bands at 1741 (—)/1735 (+)  $\text{cm}^{-1}$  for the halide-free form and at 1741 (—)/1732 (+)  $\text{cm}^{-1}$  for the halide-bound forms. Spectral downshifts by 11–13  $\text{cm}^{-1}$  were observed upon  $\text{D}_2\text{O}$  hydration. The bands probably originate from Asp115, as is the case for the wild-type and mutant BR (35). However, no additional bands were observed in Figure 4. In a previous study of the  $\text{NO}_3^-$ -bound D85S, it was suggested that Asp212 is protonated (10). Protonation of Asp212 is also reasonable for halide-bound D85S because the distance between Asp212 and halide is short (3.3 Å for  $\text{Br}^-$ , Figure 1). However, the K minus D85S spectra do not show additional bands for any halide-bound forms.

**Assignment of the N–D Stretching Vibration of the Protonated Schiff Base in D85S and Its K Intermediate in  $\text{D}_2\text{O}$ .** Figure 5 compares K minus D85S spectra between unlabeled (solid lines) and [ $\zeta$ - $^{15}\text{N}$ ]Lys-labeled (dotted lines) samples in the X–D stretching frequency region. In the halide-free D85S, two negative bands at 2280 and 2224  $\text{cm}^{-1}$  exhibit isotope shifts, indicating that they originate from N–D stretching vibrations of the Schiff base in the unpho-

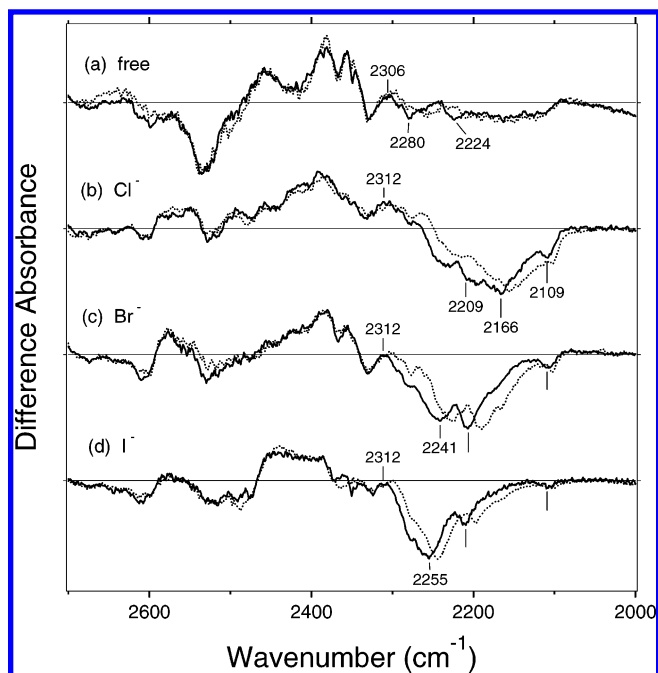

FIGURE 5: K minus D85S difference infrared spectra of halide-free (a),  $\text{Cl}^-$ -bound (b),  $\text{Br}^-$ -bound (c), and  $\text{I}^-$ -bound (d) D85S in the 2700–2000  $\text{cm}^{-1}$  region. Unlabeled (—) and [ $\zeta$ - $^{15}\text{N}$ ]Lys-labeled (····) D85S samples were hydrated with  $\text{D}_2\text{O}$ , and spectra were measured at 130 K. One division of the y axis corresponds to 0.00018 absorbance units.

tolized state (Figure 5a). Although the isotope shift was small for D85S(free), a prominent isotope shift was observed for the negative bands of halide-bound D85S. Indeed, a broad negative feature at 2300–2100  $\text{cm}^{-1}$  entirely exhibits isotope shifts of [ $\zeta$ - $^{15}\text{N}$ ]Lys-labeling, indicating that they originate from N–D stretching vibrations of the Schiff base in the unphotolyzed state (Figure 5b–d). Despite such a common spectral feature, interestingly, clear halide dependence was observed. In D85S( $\text{Cl}^-$ ), the largest negative peak appears at 2166  $\text{cm}^{-1}$  (Figure 5b). Peaks are also observed at 2209 and 2109  $\text{cm}^{-1}$ . However, two strong negative peaks appeared at 2241 and 2209  $\text{cm}^{-1}$  for D85S( $\text{Br}^-$ ) (Figure 5c), whereas an intense negative peak appeared at 2255  $\text{cm}^{-1}$  for D85S( $\text{I}^-$ ) (Figure 5d). The centers of gravity for the negative bands were calculated to be 2178, 2218, and 2239  $\text{cm}^{-1}$  for  $\text{Cl}^-$ ,  $\text{Br}^-$ , and  $\text{I}^-$ -bound forms, respectively. Thus, it is revealed that the frequency is lowered as halide becomes smaller. Such halide dependence was not clearly observed in the analysis of the C=N stretch.

It should be noted that the N–H stretching frequencies of the all-trans retinal Schiff base in  $\text{CDCl}_3$  are located at 2600, 2735, and 2957  $\text{cm}^{-1}$  in the presence of  $\text{Cl}^-$ ,  $\text{Br}^-$ , and  $\text{I}^-$ , respectively (19). Corresponding N–D stretching frequencies are located at 2150–1900  $\text{cm}^{-1}$ . Halide dependence on the N–D stretching vibration of the Schiff base in D85S was found to be similar to that in solution. In solution, the N–H (N–D) group of the Schiff base presumably forms a direct hydrogen bond with halides. Therefore, the present study strongly suggests that the Schiff base forms a direct hydrogen bond with a halide ion in D85S. The present FTIR results are consistent with the X-ray crystal structure (11).

The N–D stretching frequencies have been reported to be at 2173 and 2123  $\text{cm}^{-1}$  for BR (21), at 2488  $\text{cm}^{-1}$  for  $p\text{HR}(\text{Cl}^-)$  (at 2480  $\text{cm}^{-1}$  for  $p\text{HR}(\text{Br}^-)$ , and at 2458  $\text{cm}^{-1}$

for  $p\text{HR}(\text{I}^-)$  (22), where a lower frequency corresponds to a strong hydrogen bond. In this view, the Schiff base forms a strong hydrogen bond with halides in D85S because their N–D stretching frequencies are at 2250–2150  $\text{cm}^{-1}$ . Although the N–D stretching vibrations are halide dependent, it seems that the halide-independent peak is present. For instance, a negative band at 2109  $\text{cm}^{-1}$  is commonly observed among three halides. A negative band at 2209  $\text{cm}^{-1}$  also may be common. In contrast, peaks at 2166, 2241, and 2255  $\text{cm}^{-1}$  are unique for  $\text{Cl}^-$ ,  $\text{Br}^-$ , and  $\text{I}^-$ -bound forms, respectively. Multiple N–D stretch bands also have been reported for BR (2173 and 2123  $\text{cm}^{-1}$ ) (21) and *pharaonis* phoborhodopsin (2140 and 2091  $\text{cm}^{-1}$ ) (36).

Unlike the negative bands, a positive N–D stretch was not clearly observed in Figure 5. One possibility is that the frequency is close to those of the negative bands. In fact, the frequency differences of C=NH and C=ND stretches for the K states of D85S are larger (5–10  $\text{cm}^{-1}$ ) than that for the K state of the wild type (2  $\text{cm}^{-1}$ ), suggesting that the hydrogen bond of the Schiff base is not more weakened for D85S. No bands were actually affected by the  $[\zeta\text{-}^{15}\text{N}]$ Lys-labeled D85S sample at  $>2400\text{ cm}^{-1}$ . However, the positive band at 2306  $\text{cm}^{-1}$  in Figure 5a exhibits isotope shift upon  $[\zeta\text{-}^{15}\text{N}]$ Lys-labeling. Similarly, the positive band at 2312  $\text{cm}^{-1}$  in Figure 5b exhibits spectral downshift upon  $[\zeta\text{-}^{15}\text{N}]$ Lys-labeling. Therefore, we assign the N–D stretch of the K states of D85S(free) and D85S( $\text{Cl}^-$ ) to the 2306 and 2312  $\text{cm}^{-1}$  bands, respectively (Table 1). Regarding D85S( $\text{Br}^-$ ) and D85S( $\text{I}^-$ ), Figure 5c and d shows isotope-induced spectral downshifts for the positive 2312- $\text{cm}^{-1}$  band, though they do not appear at the positive side. We infer that it is due to the strong negative bands. Thus, we assigned that the N–D stretches of the K states of D85S( $\text{Br}^-$ ) and D85S( $\text{I}^-$ ) at 2312  $\text{cm}^{-1}$  (Table 1). On the basis of the present assignment, there is no halide dependence for the N–D stretches of the Schiff base (2312  $\text{cm}^{-1}$ ) in the K intermediate in contrast to those in the unphotolyzed state. The value is also close to that for the free-form (2306  $\text{cm}^{-1}$ ). These observations suggest that the N–D group of the Schiff base does not form a direct hydrogen bond with a halide in the K intermediate. Interestingly, a lack of halide dependence does not mean that the hydrogen bond of the Schiff base is broken because its frequency at about 2310  $\text{cm}^{-1}$  implies a hydrogen bond for the Schiff base. This may suggest that in K, the Schiff base finds another hydrogen-bonding acceptor.

**Assignment of the O–D Stretching Vibration of Water Molecules in D85S and Its K Intermediate in  $\text{D}_2\text{O}$ .** Figure 6 compares the K minus D85S spectra between samples hydrated with  $\text{D}_2\text{O}$  (red spectra) and  $\text{D}_2^{18}\text{O}$  (blue spectra) in the O–D stretching frequency region. In the halide-free D85S,  $^{18}\text{O}$ -water-induced isotope shifts are observed for the two negative bands at 2610 and 2583  $\text{cm}^{-1}$  and for a positive band at 2458  $\text{cm}^{-1}$  (Figure 6a). Two negative and one positive band are also observed at 2610, 2529  $\text{cm}^{-1}$ , and 2568  $\text{cm}^{-1}$ , respectively, for D85S( $\text{Cl}^-$ ) and D85S( $\text{Br}^-$ ) (Figure 6b and c). In contrast, only one peak pair is observed at 2610 (–)/2568 (+)  $\text{cm}^{-1}$  for D85S( $\text{I}^-$ ) (Figure 6d). There are no water bands at  $<2400\text{ cm}^{-1}$  for halide-bound forms (Figure 6b–d). In the case of D85S(free), the 2400–2200  $\text{cm}^{-1}$  region is noisy, but no clear isotope shift of water can be observed (Figure 6a). It should be noted that wild-type BR contains strongly hydrogen-bonded water molecules,

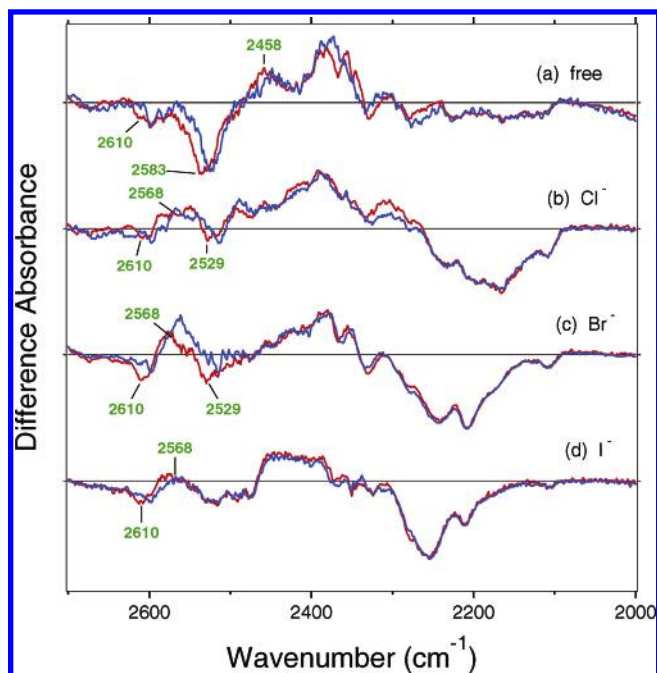

FIGURE 6: K minus D85S difference infrared spectra of the absent halide (a), containing  $\text{Cl}^-$  (b),  $\text{Br}^-$  (c), or  $\text{I}^-$ -bound (d) forms in the 2700–2000  $\text{cm}^{-1}$  region. The sample was hydrated with  $\text{D}_2\text{O}$  (red curves) or  $\text{D}_2^{18}\text{O}$  (blue curves), and spectra were measured at 130 K. Green-labeled frequencies correspond to those identified as stretching vibrations of water O–D. One division of the y axis corresponds to 0.00018 absorbance units.

whose O–D stretches are located at 2350–2150  $\text{cm}^{-1}$  (23–25). A recent FTIR study showed that strongly hydrogen-bonded water molecules are only found in rhodopsins with proton-pumping activity (27), whereas strongly hydrogen-bonded water molecules are absent in HR (28). The present results clearly show that the functionally converted mutant BR (D85S) from proton pump to halide pump does not possess strongly hydrogen-bonded water molecules, consistent with the empirical rule.

Two frequencies of water are separated by  $\sim 80\text{ cm}^{-1}$  for D85S( $\text{Cl}^-$ ) and D85S( $\text{Br}^-$ ) (Figure 6b and c). In general, a water molecule has two O–H groups, and their frequencies are distributed in the wide 3700–2700  $\text{cm}^{-1}$  region dependent on their coupling and hydrogen-bonding strength. Gaseous water exhibits asymmetric and symmetric stretching modes at 3755 and 3657  $\text{cm}^{-1}$ , respectively, and the stretching frequency is lowered because its hydrogen bond becomes stronger (37). Corresponding asymmetric and symmetric O–D stretching modes appear at about 2788 and 2671  $\text{cm}^{-1}$ , respectively (38). We thereby infer that the bands at 2610 and 2529  $\text{cm}^{-1}$  in D85S( $\text{Cl}^-$ ) and D85S( $\text{Br}^-$ ) correspond to asymmetric and symmetric stretching modes of a water molecule, respectively. Because the X-ray crystal structure of D85S( $\text{Br}^-$ ) shows the presence of a water molecule (water410) near  $\text{Br}^-$  (Figure 1), the observed water bands may originate from water410. However, the lack of halide dependence may suggest a role for another water molecule.

## DISCUSSION

The present low-temperature FTIR spectroscopic study successfully assigned the vibrational frequencies of the N–D stretch of the Schiff base and O–D stretches of internal water

molecules in D85S. In the earlier studies of vibrational analysis, the hydrogen strength of the N–H group of the protonated Schiff base was evaluated from the difference in frequencies between the C=NH and C=ND of the protonated Schiff base (14). However, this approach does not appear to be suitable for the study of halide-binding rhodopsins. Previous vibrational analysis of the C=NH and C=ND for sHR or pHR could not provide halide dependence on the hydrogen-bonding strength of the Schiff base. In contrast, in a recent FTIR study we observed clear halide dependence by analysis of N–D stretching vibrations, and a new model of the primary process of chloride transport has been established on the basis of the results (22). The estimate of hydrogen-bonding strength of the Schiff base from the C=N stretch band is probably less sensitive than that by N–D stretches for various halides.

This correlation was also the case for the BR mutant in the present study. The frequency differences between the C=NH and C=ND stretches were identical among three halides (11 cm<sup>-1</sup>; Table 1), suggesting identical hydrogen-bonding strengths. However, entirely different results were obtained from the N–D stretching vibrations of the Schiff base, where a clear halide dependence was observed. The N–D stretching frequencies were lowest for D85S(Cl<sup>-</sup>) and highest for D85S(I<sup>-</sup>), and such halide dependence was the same as the N–H stretches vibration of the all-trans retinal Schiff base in solution (19). This implies that in D85S, the Schiff base forms a direct hydrogen bond with halide. This result is consistent with the X-ray crystal structure of D85S in the presence of Br<sup>-</sup> (11).

Upon formation of the K intermediate, the halide dependence is lost for the N–D stretch bands of the Schiff base (Figure 5). These observations suggest that the N–D group of the Schiff base does not form a direct hydrogen bond with a halide in the K intermediate. Lack of halide dependence does not mean a broken hydrogen bond of the Schiff base because the frequency at about 2310 cm<sup>-1</sup> implies that the Schiff base retains a hydrogen bond. This may suggest that the Schiff base finds another hydrogen-bonding acceptor, such as Thr89, Tyr185, Asp212, or a water molecule.

Recently, we proposed a model for chloride ion pumping in pHR from the analysis of the N–D stretching vibration of the Schiff base and the O–D stretching vibrations of water molecules (22). The halide dependence of the stretching vibrations enabled us to conclude that the Schiff base forms a direct hydrogen bond with Cl<sup>-</sup> only in the K intermediate. The hydrogen bond of the Schiff base is further strengthened in the L<sub>1</sub>-intermediate, whereas halide dependence revealed that the acceptor is not Cl<sup>-</sup> but presumably a water molecule. Thus, we concluded that the hydrogen-bonding interaction between the Schiff base and Cl<sup>-</sup> is not a driving force of the motion of Cl<sup>-</sup>. Rather, the removal of its hydrogen bonds with the Schiff base and water(s) makes the environment around Cl<sup>-</sup> less polar in the L<sub>1</sub>-intermediate, which presumably drives the motion of Cl<sup>-</sup> from its binding site to the cytoplasmic domain (22). To study the mechanism of chloride transport in D85S, we have to study late photocycle intermediates. The present results suggest that the lack of halide dependence of the Schiff base in the intermediates where the crucial translocation of the halide occurs may be a key element for the chloride pump.

Previous FTIR studies of BR mutants and various rhodopsins have provided an empirical rule between strongly hydrogen-bonded water molecules and proton-pumping activity (27). In the study, we found that BR (23), *pharaonis* phoborhodopsin (39), *Leptosphaeria* rhodopsin (40), proteorhodopsin (41), and halorhodopsin in the presence of azide (42) possess strongly hydrogen-bonded water molecules (O–D stretch at < 2400 cm<sup>-1</sup> in D<sub>2</sub>O). All of them pump protons. In contrast, strongly hydrogen-bonded water molecules were not observed for halorhodopsin from *Halobacterium salinarum* and *Natronomonas pharaonis* (22, 28), *Neurospora* rhodopsin (43), *Anabaena* sensory rhodopsin (44), and bovine rhodopsin (45). None of them pump protons. In addition, various BR mutants possess strongly hydrogen-bonded water molecules if they pump protons (24, 25). Such comprehensive studies have thus revealed that strongly hydrogen-bonded water molecules are only found in the proteins exhibiting proton-pumping activities. Taken together with the present results for D85S BR mutants, this suggests that strong hydrogen-bonds of water molecules and their transient weakening is needed for the proton-pumping function of rhodopsins.

It was suggested that halide-binding into D85S yields protonation of Asp212 (10). This is reasonable, because the distance between Asp212 and halide is short (3.3 Å for Br<sup>-</sup>, Figure 1). However, the K minus D85S spectra do not show additional bands in the 1750–1700 cm<sup>-1</sup> region for any halide-bound forms (Figure 4). If Asp212 is indeed protonated, a new band should appear at this region. At this moment, there are two possibilities. One possibility is that Asp212 is deprotonated even if halide is bound inside, but then the negatively charged Asp212 must be somehow stabilized. The presence of the two positive charges, the Schiff base, and Arg82 may require deprotonation of Asp212 in addition to the bound halide. Another possibility is that Asp212 is protonated, but the C=O group does not undergo a change between the unphotolyzed and K states. Further study on late intermediates will determine the protonation state of Asp212, which is our future focus.

## ACKNOWLEDGMENT

We thank Dr. Yuji Furutani for valuable discussions.
