Received December 19, 2005; Revised Manuscript Received January 30, 2006

ABSTRACT: We reported previously that chemical modification of human α A-crystallin by a metabolic dicarbonyl compound, methylglyoxal (MGO), enhances its chaperone-like function, a phenomenon which we attributed to formation of argpyrimidine at arginine residues (R) 21, 49, and 103. This structural change removes the positive charge on the arginine residues. To explore this mechanism further, we replaced these three R residues with a neutral alanine (A) residue one at a time or in combination and examined the impact on the structure and chaperone function. Measurement of intrinsic tryptophan fluorescence and near-UV CD spectra revealed alteration of the microenvironment of aromatic amino acid residues in mutant proteins. When compared to wild-type (wt) α A-crystallin, the chaperone function of R21A and R103A mutants increased 20% and 18% as measured by the insulin aggregation assay and increased it as much as 39% and 28% when measured by the citrate synthase (CS) aggregation assay. While the R49A mutant lost most of its chaperone function, R21A/R103A and R21A/R49A/R103A mutants had slightly better function (6–14% and 10–14%) than the wt protein in these assays. R21A and R103A mutants had higher surface hydrophobicity than wt α A-crystallin, but the R49A mutant had lower hydrophobicity. R21A and R103A mutants, but not the R49A mutant, were more efficient than wt protein in refolding guanidine hydrochloride-treated malate dehydrogenase to its native state. Our findings indicate that the positive charges on R21, R49, and R103 are important determinants of the chaperone function of α A-crystallin and suggest that chemical modification of arginine residues may play a role in protein aggregation during lens aging and cataract formation.

α -Crystallin, a major structural lens protein in the eyes of vertebrates, is a multimeric protein consisting of two subunits, α A- and α B-crystallin. These subunits usually combine in a 3:1 ratio to form high molecular weight oligomers of ~800 kDa protein (*1*). The two proteins thus formed have approximately 60% amino acid sequence homology (*2*), and they belong to the small heat shock protein (sHSPs)¹ superfamily (*3, 4*). While α B-crystallin is found throughout the body, α A-crystallin is found primarily in the lens, although other tissues contain small quantities

(5–7). Several years ago it was discovered that α -crystallin exhibits a molecular chaperone-like function (*8, 9*). Like other sHSPs, α -crystallin prevents aggregation of denaturing proteins (*10*). Since α -crystallin in the lens does not turn over, posttranslational modifications presumably accumulate during aging. Numerous studies over the past few years addressed the relationship between various posttranslational modifications and the chaperone function of α -crystallin. Investigators found that posttranslational modifications such as oxidation (*11*), phosphorylation (*12*), deamidation (*13*), and glycation (*14, 15*) decreased the chaperone function of α -crystallin. Furthermore, the decreased chaperone function of α -crystallin was thought to cause protein aggregation during aging and cataract formation.

Glycation of α -crystallin is a major posttranslational modification process in the lens. The reaction begins with condensation of the carbonyl function on carbohydrates, such as sugars and ascorbate oxidation products, with an amino group of proteins (on lysine and/or the N-terminal amino acid) to form a reversible Schiff base. This derivative then undergoes rearrangement to form a relatively stable Amadori product, i.e., ketoamine. Through a series of reactions, this product forms stable adducts on proteins that are collectively known as advanced glycation end products or AGEs (*16*). AGEs form as protein cross-linking adducts or non-cross-

linking adducts, and they can be chromophoric and fluorophoric in nature. AGEs accumulate in lenses during the aging process, and they accumulate even more rapidly in cataractous lenses (17–19).

Recent studies suggest that α -dicarbonyl compounds, such as methylglyoxal (MGO) and glyoxal (GO), are major sources of AGEs in tissues (20). MGO is derived mostly from triose phosphate intermediates of glycolysis by non-enzymatic mechanisms (21). GO is derived from oxidation of several products, including sugars, ascorbate, and glycation intermediates (21). The human lens has higher concentrations of MGO than plasma (22). MGO is a highly reactive dicarbonyl compound. It reacts with arginine, lysine, and cysteine residues in proteins (23). Several modifications of MGO have been detected in the lens, including hydroimidazolones (24, 25), argpyrimidine (18, 26), methylglyoxal-lysine dimer (MOLD) (27–29), and methylglyoxal 2-ammonio-6-([2-[(4-ammonio-5-oxido-5-oxopentyl)amino]-4-methyl-4,5-dihydro-1H-imidazol-5-ylidene]amino)hexanoate (MODIC) (30). Quantification of these products shows that MGO modifications accumulate in cataractous lenses to a greater extent than in noncataractous clear lenses (31). One recent study reported several nanomolar hydroimidazolones per milligram of protein in the human lens (24), making them one of the major chemical modifications of lens proteins during aging and cataractogenesis.

Amid these seemingly harmful effects of MGO, we made the surprising observation that when MGO reacts with α A-crystallin, it enhances its chaperone function (32). We then found that Hsp27, a related sHSP, also becomes a better chaperone and a better anti-apoptotic protein after modification by MGO (32). Our studies on α A-crystallin suggested that argpyrimidine modification by MGO is the most likely reason for the enhanced chaperone function, although hydroimidazole modifications may also bring about a similar effect. Using mass spectrometric analysis of the MGO-modified α A-crystallin, we identified three arginine residues, R21, R49, and R103, that were modified by argpyrimidine. On the basis of these findings, we reasoned that neutralization of the positive charge on the guanidine group of these arginine residues by argpyrimidine modification might result in enhanced chaperone function. In fact, data derived from experiments with several arginine-modifying agents support this interpretation (32). A few arginine mutations were previously identified in α -crystallin, but they decreased chaperone function and resulted in cataract formation (33).

Those particular mutations occurred on arginine residues distinct from the MGO-modifiable ones. We interpret these findings to mean that mutations and argpyrimidine formation occur on different arginine residues and that they have opposite effects on the chaperone function of human α A-crystallin. To confirm our hypothesis, we generated a series of single and double mutants and one triple mutant of α A-crystallin in which we replaced MGO-modifiable arginine residues (R21, R49, and R103) with neutral alanine. We report the effect of these mutations on α A-crystallin structure and its chaperone function and show that such changes provide a basis for the enhanced chaperone function by MGO modification.

EXPERIMENTAL PROCEDURES

Materials. Dithiothreitol (DTT), bovine insulin, malate dehydrogenase (MDH), carbonic anhydrase (CA), citrate synthase (CS), oxaloacetic acid, and NADH were obtained from Sigma Chemical Co., St. Louis, MO. Citrate synthase was dialyzed against 40 mM HEPES buffer, pH 7.4, for 24 h before use. The reagent 2-(*p*-toluidinyl)naphthalene-6-sulfonate (TNS) was obtained from Molecular Probes (Invitrogen, Carlsbad, CA). Centrifugal filters (100 kDa cutoff) were obtained from Millipore (Bedford, MA). All other chemicals were of analytical grade.

Cloning and Site-Directed Mutagenesis. An N-terminal His tag and an enterokinase site were introduced by PCR amplification into wt α A-crystallin harbored in a pET23d vector (kindly provided by Mark Petrasch, Washington University, St. Louis, MO). The PCR reaction contained 10 ng of wt α A-crystallin pET23d as template, 1 μ M forward primer (5'-CATGCCATGGGGCACCACCACCACCAC-CACGATGACGACGACAAGATGGACGTGACCATCC-AGCAC-3') and reverse primer (5'-CCCAAGCTTAGGAC-GAGGGAGCCGAGGT-3'), 200 μ M dNTP, and 2.5 units of Pfu Turbo (Stratagene). PCR conditions were as follows: 95 °C for 5 min (1 cycle); 94 °C for 1 min, 50 °C for 1 min, 72 °C for 1 min, and 72 °C for 1 min (36 cycles); 72 °C for 10 min (1 cycle). The 560 base pair PCR product was then cloned into pET23d between *Nco*I and *Hind*III restriction sites using a Takara DNA ligation kit according to the manufacturer's instructions (Takara, Shiga, Japan).

α A-Crystallin containing the R21A mutation was generated by PCR amplification from the wt α A-crystallin in pET23d vector using the forward primer indicated in Table

1 and the same reverse primer used to generate His-tagged wt α A-crystallin (see above). The resulting PCR product containing the mutation was then used in a second PCR reaction as the mega reverse primer; the forward primer was the same as that used to generate His-tagged wt α A-crystallin. The 560 base pair PCR product encoding the R21A mutant α A-crystallin was purified, digested, and ligated into pET23d as described above. R49A, R103A, R21A/R49A, R21A/R103A, and R21A/R49A/R103A mutants of α A-crystallin were generated by a similar method, using PCR amplification and either His-tagged wt α A-crystallin or R21A α A-crystallin as templates and appropriate mutant primers (Table 1). Wild-type and mutant cDNA sequences were confirmed by restriction and DNA sequence analyses.

Protein Purification. *Escherichia coli* BL21(DE3)pLysS were transformed with plasmids containing either wt or mutant α A-crystallin cDNA. Expression of wt and mutant proteins was as follows: 500 mL of LB supplemented with ampicillin (100 μ g/mL) was inoculated with 50 mL of an overnight culture of *E. coli* BL21(DE3)pLysS harboring the appropriate vector and cultured at 37 °C, 250 rpm, until the optical density (OD) was 0.5–0.7. Induction of α -crystallin expression was initiated by addition of 250 μ M IPTG. The cultures were then grown 4–5 h longer at 37 °C, and the cells were harvested by centrifugation at 5000g for 10 min at 4 °C. Pellets were resuspended in 5 mL/g lysis buffer (100 mM NaH_2PO_4 , 10 mM Tris-HCl, 8 M urea, pH 8) and gently mixed for 1 h at room temperature. Lysates were immersed in ice and dispersed by 3×40 s bursts of sonication at 40% amplitude using a Branson digital sonifier (Danbury, CT). All samples were centrifuged at 12000g for 30 min. Each lysate was incubated with the appropriate amount of Ni-NTA resin according to the manufacturer's instructions (Qiagen, Valencia, CA) and gently mixed for 1 h at room temperature before being loaded onto a prepared column. The columns were washed with buffer (pH 7.0) containing 100 mM NaH_2PO_4 , 10 mM Tris-HCl, and 8 M urea and eluted with the same buffer at pH 5.5. The fractions were separated by SDS-PAGE, and immunoreactivity was assessed by Western blotting with an antibody to α A/ α B-crystallin as described below. Proteins that appeared as a single band at 20 kDa were pooled and extensively dialyzed at 4 °C against 50 mM Tris-HCl (pH 8.0). The pooled protein was then concentrated using Amicon Ultra-15 centrifugal filters (Millipore) and stored at –20 °C.

SDS-PAGE and Western Blotting. Four micrograms of protein and Precision protein standard (Bio-Rad Laboratories, Hercules, CA) were loaded onto two 12% SDS-PAGE gels and subjected to electrophoresis at 150 V for 1.5 h. After this time, one gel was stained with Bio-Safe Coomassie (Bio-Rad), and protein from the other was transferred electrophoretically to a nitrocellulose membrane (100 V for 1 h). The membrane was blocked by overnight incubation at 4 °C in buffer A (5% NFD in PBS). The blocked membrane was then incubated with polyclonal rabbit anti- α A/ α B-crystallin antibody in buffer A (1:3000) (Stressgen, Victoria, BC, Canada) at room temperature for 1 h. Following this initial incubation, the membrane was washed extensively with 0.05% Tween-20 in PBS and incubated for 1 h at room temperature with a 1:3000 dilution of HRP-conjugated goat anti-rabbit IgG (Sigma) in 0.05% Tween-20 in PBS along

with 1:10000 diluted Precision StrepTacin–HRP conjugate (Bio-Rad). The membrane was again washed extensively with 0.05% Tween-20, developed with SuperSignal West Pico chemiluminescent stain (Pierce, Rockford, IL), and photographed.

Determination of Molecular Mass by Dynamic Light Scattering. We used dynamic light scattering measurements to determine the molar mass of the wild-type and mutant proteins as described earlier (34). In brief, purified recombinant proteins were incubated at 37 °C for 1 h and then chromatographed on a TSK G5000PW_{XL} (Tosoh Bioscience, Inc., San Francisco, CA) size-exclusion column using phosphate buffer (0.05 M + 0.3 M NaCl, pH 7.2). The column was connected to an HPLC fitted with an RID detector (Shimadzu) and coupled to multiangle light scattering (DAWN) and quasi-elastic light scattering detectors (Wyatt Technology Corp., Santa Barbara, CA). The molar mass (M_w), polydispersity index (PDI), and hydrodynamic radius (R_h) of the samples were determined using ASTRA (5.1.5) software developed by Wyatt Technology Corp.

Circular Dichroism (CD) Measurements. The conformation of α A-crystallin was examined by recording far-UV and near-UV CD spectra at 25 °C in a Jasco 810 spectropolarimeter (Jasco, Inc.) flashed with dry nitrogen. The far-UV CD spectra were collected from 250 to 195 nm in a CD quartz cell of 1 mm path length using a slit width of 1 nm and a scan speed of 20 nm/min. The reported spectra, the average of five scans, were analyzed for secondary structure by the curve-fitting program CONTINLL (35). Far-UV CD spectra were recorded from 0.2 mg/mL proteins in 10 mM phosphate buffer (pH 7.2). Near-UV CD spectra were recorded from 1 mg/mL protein in the same phosphate buffer. Spectra were collected from 300 to 250 nm using a CD cell of 10 mm path length.

Tryptophan Fluorescence Measurements. The intrinsic tryptophan fluorescence spectrum of α A-crystallin at 25 °C was recorded in a Varian Eclipse spectrofluorometer (Varian Inc.). The fluorescence emission spectrum of each protein (0.1 mg/mL) in 50 mM phosphate buffer (pH 7.2) was recorded between 310 and 400 nm using 295 nm as the excitation wavelength. The excitation and emission band-passes were 5 nm each.

TNS Fluorescence Measurements. The surface hydrophobicity of the wild-type and mutant human α A-crystallin was studied with TNS, a specific hydrophobic probe. Ten microliters of a 10 mM methanolic solution of TNS was added to 1 mL of protein [0.1 mg/mL in 50 mM phosphate buffer (pH 7.4)], and the mixture was incubated for 2 h at 25 °C. Fluorescence emission spectra were recorded between 350 and 520 nm using an excitation wavelength of 320 nm. The excitation and emission band-passes were 5 nm each.

Chaperone-like Function of Wild-Type and Mutant Human α A-Crystallin. The chaperone-like function was determined with three target proteins: insulin, citrate synthase (CS), and carbonic anhydrase (CA). For insulin and CS, chaperone activity was assayed in 96-microwell plates using a microplate reader (SpectraMax, Model 190; Molecular Devices, Sunnyvale, CA). The total reaction volume was 250 μ L.

(a) Insulin Aggregation Assay. Insulin (0.32 mg/mL) in 50 mM phosphate buffer (pH 7.2) was incubated at 25 °C with or without wild-type (wt) or mutant α A-crystallin (0.064 mg/mL). Insulin aggregation was initiated by adding freshly

prepared DTT to a final concentration of 20 mM, and light scattering at 400 nm was monitored for 1 h in the kinetic mode (36).

(b) *CS Aggregation Assay*. CS (0.06 mg/mL in 40 mM HEPES buffer, pH 7.4) was incubated in the presence or absence of different α A-crystallin preparations at 43 °C, and light scattering was monitored at 360 nm (37). The ratio of α -crystallin to CS was 1:15 (w/w).

(c) *CA Aggregation Assay*. Six hundred microliters of CA (0.24 mg/mL) in 50 mM phosphate buffer containing 100 mM NaCl (pH 7.2) was incubated at 60 °C with or without wt or mutant α A-crystallins (0.06 mg/mL) in a Beckman DU spectrophotometer (Fullerton, CA). Light scattering at 400 nm was monitored for 1 h in a kinetic mode.

Determination of Binding Parameters between Carbonic Anhydrase (CA) and α A-Crystallin. Wild-type or mutant α A-crystallin (12.5 μ M) was incubated at 60 °C for 1 h with 2–18 μ M CA in 50 mM phosphate buffer containing 100 mM NaCl (pH 7.2). No protein aggregation was observed under these conditions. The solutions were cooled to 25 °C for 1 h. Unbound substrate was then separated by centrifugation at 4000g through 100 kDa cutoff membrane filters. The amount of remaining substrate (CA) associated with α -crystallin was calculated by subtracting free substrate from the total substrate concentration. Protein concentrations were determined by the Bradford assay using BSA as the standard. The number of binding sites (n) and dissociation constant (K_d) were determined by a similar procedure (38).

Protein Refolding Assay. Chaperone efficiency was also assessed by measuring the α -crystallin-mediated refolding of a homodimeric enzyme, malate dehydrogenase (MDH), from its fully unfolded state. MDH (1 μ M) was denatured in 6 M Gu-HCl for 8 h at 25 °C. Refolding of the enzyme was initiated by diluting the denatured MDH 100-fold in a refolding buffer (pH 7.5) containing 50 mM phosphate, 10 mM magnesium acetate, and 5 mM DTT, with or without the addition of 30 μ M α A-crystallin. The enzyme concentration was 10 nM during refolding. The activity of refolded enzyme was assayed by adding 20 μ L of refolding mixture to 580 μ L of refolding buffer that also contained 0.1 mM NADH and 0.4 mM oxaloacetate. The samples were pre-incubated at 25 °C for 10 min, and the decrease in absorbance at 340 nm with time was recorded.

RESULTS AND DISCUSSION

In our previous study (32), we discovered that modification of α A-crystallin by MGO resulted in enhanced chaperone function, and we found that this phenomenon depended upon the concentration of MGO. On the basis of immunoprecipitation experiments with a monoclonal antibody against argpyrimidine and mass spectrometric analysis of the protein, we reasoned that argpyrimidine modification at R21, R49, and R103 of α A-crystallin could explain the enhanced chaperone function. It is possible that hydroimidazolone modifications at these sites might also result in enhanced chaperone function. Soon after our discovery, another study confirmed that chaperone function of α -crystallin is improved by MGO modification (39). Furthermore, another recent study reported enhanced chaperone function of α -crystallin when a nine amino acid peptide at the N-terminus harboring R21 residue was deleted (40). Taken together, these observa-

FIGURE 1: Purification of human recombinant α A-crystallin. Four micrograms of protein was subjected to SDS–PAGE on a 12% reducing gel and then either stained with Coomassie blue (panel A) or Western blotted using a rabbit polyclonal antibody to human α A/ α B-crystallin (panel B). Lanes: 1, molecular weight markers; 2, wt α A-crystallin; 3, R21A; 4, R49A; 5, R103A; 6, R21A/R49A; 7, R21A/R103A; 8, R21A/R49A/R103A.

tions indicate that the positive charge on specific arginine residues influences the chaperone function of α -crystallin. To further investigate the role of these MGO-modifiable arginine residues in α -crystallin, we used site-directed mutagenesis to replace arginine residues at positions 21, 49, and 103 with neutral alanine residues. Even though neutralization of positive charge on arginine residues appears to be the major factor, we cannot exclude changes in physical properties such as van der Waals interaction and dipole moment and other factors such as hydrophobicity and nucleophilicity contributing to the improvement in the chaperone function of α A-crystallin.

We prepared six mutants of human α A-crystallin: R21A, R49A, R103A, R21A/R49A, R21A/R103A, and R21A/R49A/R103A as described above (Experimental Procedures). For overexpression, plasmids of wild-type and mutant human α A-crystallins were introduced into *E. coli* strain BL21-(DE3)pLysS. Protein expression was induced by the addition of IPTG. Bacterial cell pellets were solubilized by sonication in phosphate buffer containing 100 mM Na_2HPO_4 and 10 mM Tris-HCl (pH 8). This procedure yielded significant quantities of soluble wt protein, but it proved ineffective for solubilizing the mutant proteins. Since we were able to solubilize both wt and mutant proteins by sonication in the presence of 8 M urea, we used this procedure in our purification protocol. SDS–PAGE and Western blotting showed single bands, indicating that this method yielded pure proteins (Figure 1).

Multiangle light scattering coupled with size-exclusion chromatography determines polydispersity and estimates the absolute molar mass and size, which cannot be obtained by conventional chromatographic detection methods (41). Accordingly, we compared the quaternary structure, i.e., oligomeric size and molecular mass of wt and mutant proteins, by the dynamic light scattering method. Table 2 shows the estimated oligomeric sizes of various proteins. The average molar mass (M_w) and hydrodynamic radii (R_h) value of wt α A-crystallin suggest that it has a higher oligomeric size

Table 3: Percent Levels of Secondary Structure in α A-wt Protein and Its Mutants Using CONTINLL Software

	wt	R21A	R49A	R103A	R21A/ R49A	R21A/ R103A	triple
α -helix	5.7	5.3	5.8	7.4	6.9	7.5	6.9
β -sheet	38.8	40.9	38.2	38.7	39.1	38.0	39.1
β -turn	22.3	22.1	22.6	21.9	22.1	22.1	22.0
random coil	33.1	31.7	33.6	32.0	32.0	32.3	32.1

than the reported value (42, 43). The large oligomeric size of the wt protein may be due to its purification in the presence of urea. We noted that all mutants except R21A exhibited a wider mass distribution, and all except R21A and R21A/R103A had a M_w comparable to that of the wt protein. The R21A mutation rendered α A-crystallin less polydisperse, while R49A and R103A made it more polydisperse (Table 2). This suggests that R21, R49, and R103 residues have a role in α A-crystallin organization. Because all other mutants (except R21A) had higher hydrodynamic radii (R_h) values, we believe that they are less dynamic than wt protein. Overall, our findings suggest that the removal of the positive charge from R49 and R103 results in higher molecular weight homoaggregates of α A-crystallin. This is similar to observations made for the two arginine mutants, R116C in α A-crystallin and R120G in α B-crystallin, where it was noted that arginine residues at these positions are essential for maintaining proper oligomeric structure (44, 45).

We probed the secondary structure of wt and mutant α A-crystallins by far-UV circular dichroism. All of the spectra reflect characteristics of dominant β -sheet structure. The spectra were quantitatively analyzed using the CONTINLL program. The estimated levels of secondary structure are listed in Table 3. The values suggest that there is no significant change in the secondary structure in any of the mutant proteins. We also studied the effect of mutation on the secondary structure using Fourier transform infrared spectroscopy (data not shown). The data confirmed the results from far-UV measurements indicating that our selected mutations did not perturb the secondary structure of proteins.

The near-UV CD spectra of the six mutants and wt α A-crystallin are shown in Figure 2. The near-UV spectrum of the wt protein exhibited five distinct maxima (around 259, 264, 272, 279, and 287 nm) and five distinct minima (around 262, 268, 275, 283, and 292 nm), which are consistent with previously published results (46). The signal for Phe in the 250–270 nm region showed minimal alteration in the six mutants compared to the wt protein. However, peaks beyond 270 nm for all six mutants were significantly different both in intensity and in position from those for wt protein. These marked changes in spectral characteristics of six mutants suggest alteration of the microenvironments of Tyr and/or Trp and indicate that the tertiary structure of the mutant proteins could be changed by substitution of alanine for the charged arginine residues.

Intrinsic fluorescence spectra of the wt and mutant α A-crystallins (Figure 3) support our near-UV CD data. While the fluorescence intensity of R49A, R21A/R49A, and R21A/R49A/R103A decreased ~12–14% compared to the wt protein, it increased slightly in R21A, R21A/R103A, and R103A. Alteration in fluorescence emission maxima was also noticeable. The fluorescence emission maximum (λ_{max}) of

FIGURE 2: Near-UV circular dichroic spectra of human α A-crystallin. Proteins (1.0 mg/mL) were in 10 mM phosphate buffer (pH 7.2) at 25 °C. Spectra were measured in a 10 mm path length CD quartz cell. Data were collected at 0.4 nm wavelength resolution.

FIGURE 3: Intrinsic fluorescence spectra of human α A-crystallin. The fluorescence spectrum of different samples (0.1 mg/mL protein) was recorded from 310 to 400 nm at 25 °C. The excitation wavelength was 295 nm. Data were collected at 0.5 nm wavelength resolution.

wt α A-crystallin was at 344 nm. We found that the λ_{max} of six mutants exhibited an ~2 nm blue shift, which suggests that the tryptophan microenvironment is somewhat altered in all mutant proteins. These observations support our previous conclusions that minor structural changes enhance the chaperone function of α A-crystallin (32).

We explored the effect of structural changes on the chaperone-like activity of wt α A-crystallin and six mutant proteins using two target proteins, insulin and citrate synthase. Figure 4A shows the profile of DTT-induced insulin aggregation in the presence or absence of wt and mutant α A-crystallins. At a 1:5 (w/w) ratio of wt α A-crystallin to insulin and 1 h incubation, we noted ~30% of protection against aggregation (Figure 4A, trace 4, and 4C). At the same

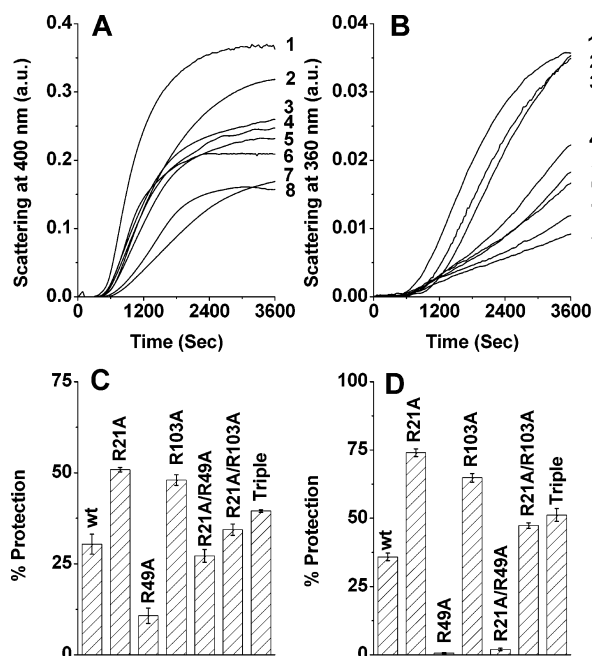

FIGURE 4: Chaperone function of human α A-crystallin. DTT-induced aggregation of 0.32 mg/mL insulin at 25 °C (panel A) and thermal aggregation of 0.06 mg/mL CS at 43 °C (panel B) in the presence or absence of different α A-crystallin preparations. Traces: 1, target protein (TP) alone; 2, TP + R49A; 3, TP + R21A/R49A; 4, TP + wt; 5, TP + R21A/R103A; 6, TP + triple (R21A/R49A/R103A); 7, TP + R103A; 8, TP + R21A. Panels C and D show the percent protection ability of different α A-crystallins against insulin and CS aggregation. The chaperone:substrate ratio (w/w) was 1:5 and 1:15 for insulin and CS aggregation assays. Data are the means \pm standard deviation from triplicate determinations.

protein ratio, R21A and R103A markedly increased chaperone function, providing 50% and 48% protection (Figure 4A, traces 7 and 8, and 4C). In contrast, R49A and R21A/R49A mutants decreased chaperone function and provided only \sim 11% and \sim 27% protection against insulin aggregation (Figure 4A, traces 2 and 3, and 4C). The double mutant R21A/R103A and the triple mutant R21A/R49A/R103A afforded slightly better protection than wt α A-crystallin (Figure 4C). With CS as the target protein, we saw a more dramatic effect. At a chaperone:substrate ratio of 1:15 (w/w), R49A (Figure 4B, trace 2) and R21A/R49A (Figure 4B, trace 3) inhibited protein aggregation minimally. At the same ratio, R21A and R103A inhibited protein aggregation 39% and 28% better than wt α A-crystallin (Figure 4B, traces 7 and 8, and 4D). We also compared the chaperone function of wt and six mutant proteins by varying the α -crystallin:substrate ratio. In each case, we found the R21A and R103A mutants to be better than the wt and R49A to be less effective than the wt in preventing aggregation of the target protein (data not shown). Taken together, these data suggest that a significant loss in chaperone function occurs when the positive charge on R49 is removed, but an opposite and favorable increase in chaperone function occurs with removal of positive charge on R21 and R103. The strength of the chaperone function decreases in the following order: R21A > R103A > R21A/R49A/R103A > R21A/R103A > wt > R21A/R49A > R49A. We believe that this is the first report of an increase in the chaperone function of α -crystallin due to removal of a single arginine residue without changes in

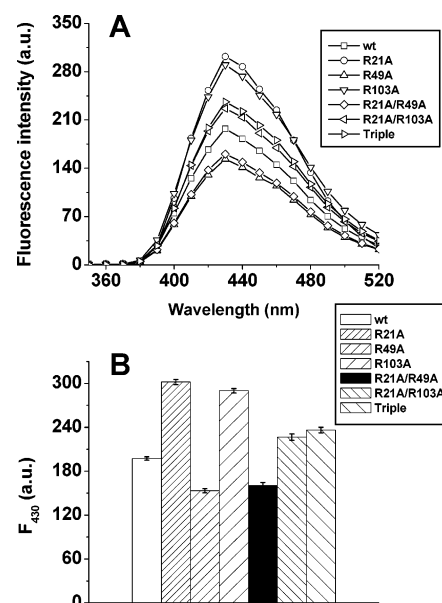

FIGURE 5: (A) Fluorescence spectra of TNS-bound α A-crystallin. The protein concentration was 0.1 mg/mL, and the TNS concentration was 100 μ M. The fluorescence spectrum of different samples at 25 °C was recorded from 350 to 520 nm. The excitation wavelength was 320 nm. (B) Fluorescence intensity at 430 nm (emission maxima) for wt and mutant α A-crystallin at 25 °C.

the secondary structure detected by CD spectra and tryptophan fluorescence. We think that the improved chaperone function reported by Pasta et al. (40) in deletion mutants of α -crystallin may be due to removal of the R21 residue from the N-terminal end of the protein.

Numerous studies suggested a correlation between chaperone function and surface-exposed hydrophobicity in α -crystallin (38, 47–50), but a few others failed to find such a correlation (51, 52). Notwithstanding this controversy, it is generally believed that surface hydrophobicity governs the chaperone function of α -crystallin. Accordingly, we used TNS, a hydrophobic molecule (with low fluorescence quantum yield in water), to explore how mutation of arginine residues affects the hydrophobicity of α A-crystallin. When TNS binds to hydrophobic sites on proteins, its quantum yield dramatically increases (53). This dye has been widely used for probing the surface hydrophobicity of α -crystallin (13, 44, 54). Figure 5A shows fluorescence measurements of TNS after binding to wt and mutant α A-crystallins. Upon binding to the wt α A-crystallin TNS displays intense fluorescence with an emission maximum (λ_{max}) at 430 nm. This λ_{max} did not change in mutant proteins. The results suggest that R21A and R103A both have \sim 55% more hydrophobic surface area compared to the wt α A-crystallin (Figure 5) and the triple mutant has \sim 20% more. In contrast, R49A and R21A/R49A mutant proteins had decreased (\sim 26% and 18%) surface hydrophobicity (Figure 5). The surface hydrophobicity of our selected mutants decreased in the following order: R21A > R103A > R21A/R49A/R103A > R21A/R103A > wt > R21A/R49A > R49A (Figure 5B). The decreasing order of the surface hydrophobicity coincides with decreasing chaperone function. From these results, we could conclude that the enhanced chaperone function of mutant proteins was due to increased surface hydrophobicity. However, this interpretation conflicts with the results of two previous studies, where MGO-mediated enhancement in chaperone function did not

FIGURE 6: Inhibition of thermal aggregation of carbonic anhydrase (CA). CA was incubated at 60 °C for 1 h in 50 mM phosphate buffer (pH 7.2) containing 100 mM NaCl in the presence or absence of indicated proteins. Light scattering due to protein aggregation was monitored at 400 nm. Traces: 1, 0.24 mg/mL CA alone; 2, CA + 0.06 mg/mL R49A; 3, CA + 0.06 mg/mL wt; 4, CA + 0.06 mg/mL R103A; 5, CA + 0.06 mg/mL R21A.

correlate with surface hydrophobicity of α -crystallin (32, 39). Possibly MGO modification (and ensuing cross-linking) of α -crystallin impedes the binding of hydrophobic probes.

To determine how the interaction between α A-crystallin and denaturing substrates would be affected by arginine mutations, we measured the binding parameters using carbonic anhydrase (CA) as the substrate. Before determining the binding constant and number of binding sites (n), we first compared the chaperone activity of wt and mutant α A-crystallin proteins using CA as the target protein. We used only three single mutants for these experiments. Figure 6 shows the thermal aggregation profile of 0.24 mg/mL CA at 60 °C in the presence or absence of wt and mutant α A-crystallin (0.06 mg/mL). The chaperone function followed the same pattern as the insulin and CS aggregation assays, proceeding from highest to lowest in the following order: R21A > R103A > wt > R49A. To determine binding constants, we incubated 12.5 μ M α A-crystallin at 60 °C for 1 h with varying concentrations (2–18 μ M) of CA. Unbound (S) and bound CA were measured by filtration as described above under Experimental Procedures. Assuming that there are identical noninteracting sites per subunit of the chaperone, the dissociation constant (K_d) was analyzed by the Scatchard equation:

$$\tilde{\nu}/S = n/K_d - 1/K_d \tilde{\nu} \quad (1)$$

where $\tilde{\nu}$ is the number of moles of substrate bound per mole of chaperone, n is the number of binding sites, and K_d is the dissociation constant. The stoichiometry n and K_d obtained from the plot of $\tilde{\nu}/S$ against $\tilde{\nu}$ (Figure 7) is 2.32 per subunit of α A-crystallin and 3.87 μ M, respectively (Table 4). When R21A interacts with CA, we found that the number of binding sites (n) per subunit increased considerably (from 2.32 to 3.73) and the association constant increased from 0.258 μ M⁻¹ (K_d = 3.87 μ M) to 0.342 μ M⁻¹ (K_d = 2.92 μ M). The binding parameters for the interaction between CA and R103A also indicate enhanced CA binding. In contrast, we found that the number of binding sites (n) for CA on R49A decreased significantly (from 2.63 to 1.79), although the dissociation constant (K_d) for this interaction was quite

FIGURE 7: Binding constant of α A-crystallin for carbonic anhydrase. Scatchard plot to calculate binding parameters for the interaction between CA and different recombinant α A-crystallins at 60 °C.

Table 4: Determination of n and Dissociation Constant (K_d) Values for Interaction of Human α A-Crystallin and Its Mutants with Carbonic Anhydrase (CA) at 60 °C

system studied	n	K_d (μ M)
human α A-crystallin + CA	2.32 ± 0.06	3.87 ± 0.30
R21A + CA	3.73 ± 0.09	2.92 ± 0.24
R49A + CA	1.67 ± 0.02	3.82 ± 0.15
R103A + CA	3.04 ± 0.07	2.33 ± 0.17

similar to that of wt α A-crystallin. On the basis of these data, we conclude that substitution of alanine for charged arginine residues at positions 21 and 103 provides higher affinity toward denaturing proteins for α A-crystallin.

α -Crystallin also assists in the *in vitro* refolding of many enzymes (55–58). As a measure of this activity, we examined the ability of wt and mutant α A-crystallins to reactivate fully denatured malate dehydrogenase (MDH). MDH was renatured by 100-fold dilution from 6 M Gu-HCl to refolding buffer, and refolding was measured in the presence or absence of α A-crystallin (Figure 8). In the absence of α A-crystallin, only 3% activity was recovered (trace 5). In the presence of 30 μ M wt α A-crystallin about 41% activity of MDH could be regained (trace 3). R21A and R103A mutant proteins at the same protein concentration provided a further increase of 9% and 4% (traces 1 and 2). As expected, the recovery of enzyme activity with R49A was drastically reduced (~13% less than with wt α A-crystallin) (trace 4). Thus, both aggregation and refolding activity assays show that mutation of charged R21 and R103 markedly enhances the chaperone function of α A-crystallin, while mutation of R49 decreases it.

We noted that the increase in chaperone function does not correspond quantitatively with enhanced surface hydrophobicity. For example, the R21A mutant protein enhanced hydrophobicity more than 55% but only increased refolding approximately 10% (Figure 8, trace 1). The insulin aggregation assay for the same protein indicates an ~20% increase in chaperone activity above that of the wt α A-crystallin (Figure 4C). This anomaly could be explained if the hydrophobic probe, TNS, binds to all of the exposed hydrophobic patches, but not all of them are accessible or large enough to accommodate the target protein.

FIGURE 8: Reactivation of malate dehydrogenase (MDH) by α A-crystallin. MDH was inactivated by incubation at 25 °C in 6 M Gu-HCl solution. Traces: 5, 10 nM MDH alone; 4, 10 nM MDH + 30 μ M R49A; 3, 10 nM MDH + 30 μ M wt; 2, 10 nM MDH + 30 μ M R103A; 1, 10 nM MDH + 30 μ M R21A. Refolding was initiated by 100-fold dilution of MDH (1 μ M) in 6 M Gu-HCl in refolding buffer (pH 7.5) containing 50 mM phosphate, 10 mM magnesium acetate, and 5 mM DTT. Each data point is the average of triplicate measurement, and error bars denote standard deviation.

The correlation between oligomeric size and chaperone function of α -crystallin is still unclear. Several previous studies showed that increased oligomeric size diminishes chaperone function (44, 45), whereas others indicated the opposite, that greater oligomeric size enhances chaperone function (34, 59). Our own studies failed to indicate a correlation between the oligomeric size and chaperone function of α A-crystallin. Because protein turnover within the lens is negligible, we speculate that oligomerization provides the structural stability necessary for α -crystallin to maintain its chaperone function for many years.

Our results suggest that each of the positive charges on R21, R103, and R49 sites in α A-crystallin are important for chaperone function. The R49A mutation seems to have a strong negative effect on the chaperone function, which was not overcome by inclusion of a R21A mutation, even though mutation at R21A alone significantly increased the chaperone function of α A-crystallin. The triple mutant, unlike the double mutant R21A/R49A, was a much better chaperone than the wt α A-crystallin, suggesting that mutation at R103A has the strongest positive effect on the chaperone function of α A-crystallin. The influence of R103A appears even greater than the R21A mutation.

Although reaction with MGO changes the charge on all three arginine residues, the overall effect is most likely a gain of function, as evident from the behavior of the triple mutant R21A/R49A/R103A. Our studies provide an explanation for the MGO-induced enhancement in chaperone function of α A-crystallin. It seems likely that MGO-induced changes help to maintain the chaperone function of α -crystallin during aging and cataractogenesis.

ACKNOWLEDGMENT

We thank Witold Surewicz, Michael Zagorski, and Clemens Burda of Case Western Reserve University, Cleveland, OH, for use of the FTIR, CD spectropolarimeter, and fluorescence spectrofluorometer. We are grateful to Dr. J. Mark Petrash, Washington University, St. Louis, MO, for the human α A-crystallin-pET23d vector.
